October, 2017.

#### Abstract

We propose a new identification and estimation strategy for the Regression Discontinuity Design (RDD). Our approach explores the heterogeneity in the "first stage" discontinuities for different values of a covariate to generate over-identifying restrictions. This allows us to identify quantities which cannot be identified with the standard RDD method, including the effects of multiple endogenous variables, multiple marginal effects of a multivalued endogenous variable, and heterogeneous effects conditional on covariates. Additionally, when this method is applied in the standard RDD setting (linear model with a single endogenous variable), identification relies on a weaker relevance condition and has robustness advantages to variations in the bandwidth and heterogeneous treatment effects. We propose a simple estimator, which can be readily applied using packaged software, and show its asymptotic properties. Then we implement our approach to the problem of identifying the effects of different types of insurance coverage on health care utilization, as in Card, Dobkin and Maestas (2008). Our results show that Medicare eligibility affects health care utilization both through the extensive margin (i.e., one insurance vs. no insurance) and the intensive margin (i.e., more generous insurance vs. less generous insurance). While the extensive margin affects the utilization of recurrent, lower cost, care (e.g., doctor visits), the intensive margin affects the utilization of sporadic, higher cost, care (e.g., hospital visits).

[^0]
## 1 Introduction

Regression Discontinuity Design (RDD) has emerged as one of the most credible identification strategies in the social sciences; see Imbens and Lemieux (2008) and Lee and Lemieux (2010) for early surveys of the literature and Cattaneo and Escanciano (2017) for a more recent overview. We propose a new method of identification and estimation in the RDD setting which uses the variations on the first stage discontinuities of the endogenous variable(s) at the threshold for different values of a covariate. Since the covariate can be multivalued, this generates over-identifying restrictions, which can be leveraged in several directions unexplored in the standard RDD setting. Our paper relates to a number of papers discussing the inclusion of covariates in the standard RDD setting; see, e.g., Imbens and Lemieux (2008), Frolich (2007) and Calonico, Cattaneo, Farrell and Titiunik (2016). The specific way in which we include the covariates is new. We show that covariates can be used to improve identification in the standard RDD setting as well as to achieve identification in settings in which the standard RDD cannot be used at all, as we discuss next.

Although the RDD literature has been mainly focused on the case of a binary treatment variable, there are many applications of the RDD methodology where the treatment variable of interest can take multiple values; see, for example, empirical applications in Angrist and Lavy (1999), Chay and Greenstone (2005), Ludwig and Miller (2007), Card, Dobkin and Maestas (2008), Carpenter and Dobkin (2009) and Brollo, Nannicini, Perotti and Tabellini (2013), among others. In such cases the standard RDD identifies the compound effect of all the changes, but not the specific effects. Thus, for example, if there are two treatment levels, the RDD identifies a weighted average of the effects of the changes in both treatment levels, but not the effect of each treatment level separately. To the best of our knowledge, this article proposes the first identification and estimation strategy for RDD with multiple treatment variables. ${ }^{1}$ This includes cases in which there are multiple endogenous variables, one multivalued endogenous variable with varying marginal effects, and models with varying coefficients (heterogeneous effects) conditional on covariates.

In the standard RDD setting (linear model with a single endogenous variable), our approach can achieve identification when the expected value of treatment conditional on a covariate varies with the covariate, even if on average the expected value of treatment is the same across the threshold and thus a standard RDD approach would not be able to identify the treatment effect. When both approaches can be applied, our estimation strategy has efficiency advantages due to its over-identifying restrictions, leading to smaller mean squared errors that are less sensitive to the bandwidth choice.

We apply our approach to the problem of estimating the effects of insurance coverage on health care utilization with a regression discontinuity design, as in Card, Dobkin and Maestas (2008). They exploit the fact that Medicare eligibility varies discontinuously at age 65 . Medicare eligibility may affect health care utilization via two channels: (1) the extensive margin, because Medicare eligibility provides coverage to people who were previously uninsured, and (2) the intensive margin, because it provides more generous coverage to people who were previously insured by other, less generous,

[^1]insurance policies. We find that minorities and lowly educated persons are more likely to be affected by Medicare eligibility in the extensive margin (i.e., one insurance vs. no insurance), while Whites and highly educated persons are more likely to be affected by Medicare eligibility in the intensive margin, (i.e., more generous vs. less generous insurance). We show that using our approach to exploit this heterogeneity in the first stage allows us to identify the partial effects at both these margins. While the extensive margin seems to matter for recurrent, lower cost care, utilization (e.g., doctor visits), the intensive margin seems to matter for sporadic, higher cost, utilization (e.g., hospital visits).

The paper is organized as follows. Section 2 develops our approach as well as the identification conditions. Section 3 presents the estimator and its asymptotic behavior, as well as a simple implementation strategy. Section 4 reports the results of Monte Carlo experiments, including comparisons to the standard RDD in the cases when both approaches could be applied. Section 5 presents the application of our method to the problem of identifying the effects of different types of insurance coverage on health care utilization. Finally, we conclude in Section 6. An Appendix contains general results on identification and proofs of the identification and asymptotic results.

## 2 Identification

We begin with a simple model with homogeneous (in covariates) marginal effects for exposition purposes. See the Appendix Section A for a more general model, and Section 2.3 for a very applicable model with variable marginal effects. Consider the following model for the outcome variable $Y_{i}$,

$$
\begin{equation*}
Y_{i}=g\left(T_{i}, W_{i}\right)+h\left(Z_{i}, W_{i}, \varepsilon_{i}\right), \tag{1}
\end{equation*}
$$

where $T_{i}$ is a treatment variable, whose effects summarized in $g$ are of interest, $Z_{i}$ is a vector of covariates, $W_{i}$ is the so-called running variable, and $\varepsilon_{i}$ is an unobservable error term. We assume that $T_{i}$ is multivalued, with discrete support $\mathcal{T}=\left\{t_{0}, \ldots, t_{d}\right\}, d<\infty$, and where $t_{0}<t_{1}<\cdots<t_{d}$. Define the $d$-dimensional vector $X_{i}=\left(1\left(T_{i}=t_{1}\right), \ldots, 1\left(T_{i}=t_{d}\right)\right)^{\prime}$, where $1(A)$ denotes the indicator function of the event $A$ and $B^{\prime}$ denotes the transpose of $B$. Define $\alpha(w)=g\left(t_{0}, w\right)$, and define the vector of marginal effects $\beta(w)=\left(g\left(t_{1}, w\right)-g\left(t_{0}, w\right), \ldots, g\left(t_{d}, w\right)-g\left(t_{d-1}, w\right)\right)^{\prime}$, where $w$ is in the support of $W_{i}$. So, the $j$-th component of $\beta(w)$ represents the marginal effect of moving from treatment level $t_{j-1}$ to $t_{j}$ at $W_{i}=w$ (e.g., in our application $\beta_{1}$ represents the marginal effect of going from $t_{1}=1$ (one health insurance policy) to $t_{2}=2$ (two or more health insurance policies) at the age of 65 , i.e. $w=65$. Then, noting that

$$
g\left(T_{i}, W_{i}\right)=g\left(t_{0},, W_{i}\right)+\left[g\left(t_{1}, W_{i}\right)-g\left(t_{0}, W_{i}\right)\right] 1\left(T_{i}=t_{1}\right)+\cdots+\left[g\left(t_{d}, W_{i}\right)-g\left(t_{d-1}, W_{i}\right)\right] 1\left(T_{i}=t_{d}\right)
$$

and defining $H_{i}=\alpha\left(W_{i}\right)+h\left(Z_{i}, W_{i}, \varepsilon_{i}\right)$, the model can be succinctly written as

$$
\begin{equation*}
Y_{i}=\beta\left(W_{i}\right) X_{i}+H_{i}, \tag{2}
\end{equation*}
$$

where $\beta(\cdot)$ is the parameter of interest, and the distribution of $H_{i}$ given $X_{i}$ and $W_{i}$ are nuisance parameters. We further assume that the running variable $W_{i}$ is univariate and continuously distributed. Note
that the results that follow are all based on equation (2), and thus they are also valid for an arbitrary vector $X$ (not necessarily a vector of binary indicators), provided that equation (2) holds. Thus, for example, if one is interested in the effects of having an additional alcoholic drink on mortality rates in a linear model, as in Carpenter and Dobkin (2009), all our results apply directly and, importantly, allow for heavy drinking to have a larger marginal effect on mortality rates than mild drinking. ${ }^{2}$

A key assumption in the RDD literature is the continuity of the distribution of $H_{i}$ given $W_{i}$ at a certain threshold point $w_{0}$ in the support of $W_{i}$. This continuity is implied by the following condition, which is convenient for our purposes.

Assumption $1 E\left[H_{i} \mid W_{i}=w, Z_{i}\right]$ and $\beta(w)$ are continuous in $w$ at $w_{0}$ almost surely (a.s.). ${ }^{3}$
Denote the parameter of interest by $\beta_{0}=\beta\left(w_{0}\right)$. Assumption 1, equation (2), and the existence of the limits involved imply the equation

$$
\begin{equation*}
\delta_{Y}(Z)=\beta_{0}^{\prime} \delta_{X}(Z) \tag{3}
\end{equation*}
$$

where, for a generic random vector $V$,

$$
\delta_{V}(Z)=\lim _{w \downarrow w_{0}} E[V \mid W=w, Z]-\lim _{w \uparrow w_{0}} E[V \mid W=w, Z] .
$$

Equation (3) is key in our analysis as it relates reduced form effects $\delta_{X}(Z)$ and $\delta_{Y}(Z)$ with the structural parameters of interest. To simplify the notation, we drop the dependence on $Z$ of $\delta_{V}(Z)$.

The following condition guarantees a unique solution of equation (3).
Assumption $2 E\left[\delta_{X} \delta_{X}^{\prime}\right]$ is positive definite.
Assumption 2 requires that the $X$ s change across the threshold in a linearly independent manner for different values of $Z$. Indirectly, it requires that $Z$ assumes at least $d$ values, as we show below. The following result establishes the conditions for identification of $\beta_{0}$.

Theorem 2.1 Let equation (2) and Assumption 1 hold. Then, $\beta_{0}$ is identified iff Assumption 2 holds.

Note that Assumption 2 is the minimal condition for identification in this model. Other identification conditions, such as for example the local version of Assumption 2 given by

$$
E\left[\delta_{X} \delta_{X}^{\prime} \mid W=w_{0}\right] \text { is positive definite, }
$$

are sufficient but not necessary for identification, and as such are stronger than Assumption 2. Theorem 2.1 is a special case of a more general identification result derived in Section A of the Appendix. There, we establish a necessary and sufficient condition for identification in a general version of the model in (1) that allows for marginal effects that depend on $Z$. The conclusion of the Theorem remains true if $X$ and $Z$ are continuous, discrete or mixed, as long as (2) holds. In the following three subsections we develop special cases which clarify the identification requirements as well as why the identification works. All these cases are particularly relevant in practice.

[^2]
### 2.1 Single Binary Treatment Variable (Standard RDD)

Consider the case of a single binary treatment variable (i.e. $d=1$ ), with support $\mathcal{T}=\{0,1\}$. This is the standard RDD setting, and thus both the standard RDD and our approach can achieve identification of $\beta_{0}$, but the relevance condition is different. In our approach, Assumption 2 requires $E\left[\delta_{X}^{2}\right] \neq 0$, which means that

$$
\delta_{X}=\lim _{w \downarrow w_{0}} P(T=1 \mid, Z, W=w)-\lim _{w \uparrow w_{0}} P(T=1 \mid Z, W=w) \neq 0 \text { with positive probability. }
$$

The standard RDD relevance requires $\lim _{w \downarrow w_{0}} P(T=1 \mid W=w)-\lim _{w \uparrow w_{0}} P(T=1 \mid W=w) \neq 0$ which is equivalent to $\lim _{w \downarrow w_{0}} E[P(T=1 \mid Z, W=w)]-\lim _{w \uparrow w_{0}} E[P(T=1 \mid Z, W=w)]=E\left[\delta_{X}\right] \neq 0$ (by the law of iterated expectations and the Dominated Convergence Theorem). Thus, the standard RDD relevance is stronger than our Assumption 2.

In other words, our approach uses the variation of the differential in the probability of treatment across the threshold for different values of the covariate $Z$, whereas the standard RDD relies exclusively on the variation of the average differential in the probability of treatment across the threshold for the different values of $Z$. To better understand the implications of our relevance condition, consider the following simplified example. Suppose $\delta_{X}$ is a linear function of $Z, \delta_{X}=\alpha_{1}+\alpha_{2} Z$, with $Z$ a random variable with zero mean. A standard RDD approach requires $\alpha_{1} \neq 0$ for identification, while our design requires $\alpha_{1} \neq 0$ or $\alpha_{2} \neq 0$. Our approach allows cases in which for a subset of values of $Z$ the probability of treatment increases across the threshold, while for other values it decreases, even if these cancel out so that on average there is no change at all.

Moreover, let $q$ be the cardinality of the support of $Z$. Then the standard RDD equation $\mathbb{E}\left[\delta_{Y}\right]=$ $\beta_{0} \mathbb{E}\left[\delta_{X}\right]$ provides just-identification, while the equation $\delta_{Y}=\beta_{0} \delta_{X}$ provides in general $q-1$ overidentification restrictions. Practically, this translates into smaller mean squared errors for estimators based on our identification strategy and mean squared errors that are far less sensitive to bandwidths than standard RDD estimators. Our Monte Carlo Section 4 illustrates this point. Additionally, having over-identification restrictions enables researchers to test the constancy of the marginal effects in $Z$, for example, by estimating and comparing covariate specific marginal effects using standard RDD methods when sample sizes are large, or using more practical tests that we discuss in Section 2.3 when sample sizes are moderate or small.

### 2.2 RDD with Two Treatment Variables

Consider the case of two treatment variables (i.e. $d=2$ ), i.e. $X=\left(X_{1}, X_{2}\right)^{\prime}$. It is straightforward to extend the intuition of this case to more complex cases in which there are more treatment variables, as well as to the case of multiple arbitrary variables in a linear model described by equation (2). In this setting the standard RDD cannot identify the separate effect of each of the variables, and thus there is no comparison to be made between the two methods.

The main identifying equation reads $\delta_{Y}=\beta_{1} \delta_{X_{1}}+\beta_{2} \delta_{X_{2}}$, where $\beta_{0}=\left(\beta_{1}, \beta_{2}\right)^{\prime}$. Assume for exposition ease that the support of $Z$ is finite, given by $\left\{z_{1}, \ldots, z_{q}\right\}$. If $\delta_{X_{2}}\left(z_{j}\right)=0$ for all $j=1, \ldots, q$, then Assumption 2 fails and $\beta_{2}$ is unidentified. In a double treatment level model, Assumption 2 implies
that there must be a change in the probability of the second treatment level $\lim _{w \downarrow w_{0}} P\left(X_{2}=1, Z=\right.$ $\left.z_{j}, W=w\right)-\lim _{w \uparrow w_{0}} P\left(X_{2}=1 \mid Z=z_{j}, W=w\right)$ for at least one value of $j$. In the more interesting case where there is a discontinuity in $X_{2}$, i.e. $\delta_{X_{2}}\left(z_{j}\right) \neq 0$ for some $j=1, \ldots, q$, Assumption 2 holds provided that for at least two values of $j$ there is no $\lambda$ such that $\delta_{X_{1}}\left(z_{j}\right)=\lambda \delta_{X_{2}}\left(z_{j}\right)$. In a double treatment level model, this translates into the requirement that the changes in the probabilities of the first and second treatment levels cannot always be proportional. This is the precise differential effect to which we referred above.

In our application example (see Section 5) the relevance condition translates into the requirement that when crossing the Medicare eligibility age requirement at 65 , the increase in insurance coverage from zero to one insurance policies and from one to two or more insurance policies cannot be proportional for all the values of education and ethnicity. This condition holds, since indeed Minorities and lowly educated persons tend to shift from zero to one insurance policy proportionally more than Whites and highly educated persons, while the opposite happens from one insurance policy to two or more insurance policies. The idea is thus to explore these linearly independent shifts to disentangle the effect of having one insurance versus none, from the effect of having two or more insurances versus one insurance.

Assumption 2 is thus testable, as its empirical counterpart can be calculated directly. We also recommend visual checks for a sample version of the rank condition $\delta_{X_{1}}\left(z_{j}\right) \neq \lambda \delta_{X_{2}}\left(z_{j}\right)$, see for example Figure 4 in Section 5. It is evident from the figure that $\delta_{X_{1}}\left(z_{1}\right) / \delta_{X_{2}}\left(z_{1}\right) \neq \delta_{X_{1}}\left(z_{2}\right) / \delta_{X_{2}}\left(z_{2}\right)$, where $z_{1}$ denotes highly educated Whites and $z_{2}$ denotes low educated Minorities. This implies the lack of proportionality mentioned above, and hence the validity of Assumption 2 in this application.

More generally, if $X$ is $d$-dimensional and $Z$ is discrete with $q$ points of support, our Assumption 2 translates into a simple rank condition as follows. Let $\Delta_{X}$ denote the $q \times d$ matrix with $j$-th row equals to $\delta_{X}\left(z_{j}\right), j=1, \ldots, q$, so that $\Delta_{Y}=\Delta_{X} \beta_{0}$. Then, by the Rank Nullity Theorem, a necessary and sufficient condition for identification of $\beta_{0}$ is that

$$
\begin{equation*}
\operatorname{rank}\left(\Delta_{X}\right)=d \tag{4}
\end{equation*}
$$

The necessary order condition is $q \geq d$, and the number of over-identifying restrictions is $q-d$.
To see this, note that

$$
\begin{equation*}
E\left[\delta_{X} \delta_{X}^{\prime}\right]=\Delta_{X}^{\prime} L \Delta_{X} \tag{5}
\end{equation*}
$$

where $L$ is a diagonal $q \times q$ matrix with $j$-th diagonal element $\operatorname{Pr}\left(Z=z_{j}\right) / q$. It is then clear that Assumption 2 is equivalent to (4), since $L$ has full rank and by (5), $\operatorname{rank}\left(E\left[\delta_{X} \delta_{X}^{\prime}\right]\right)=\operatorname{rank}\left(\Delta_{X}\right)$.

Our empirical example below considers the case of $d=2$ and $q=6$. The number of over-identifying restrictions is $q-d=4$ in this example. As we will see in the next section, having over-identifying restrictions enables researchers to test the hypothesis of constant marginal effects with respect to covariates.

### 2.3 Variable Marginal Effects

Assume now that marginal effects are a linear function of $Z_{1}$, where $Z=\left(Z_{1}, Z_{2}\right)$. Specifically, assume that the $j$-th component of $\beta_{0}$ is given by

$$
\beta_{j}=\gamma_{0 j}+\gamma_{1 j} Z_{1}
$$

where we assume, for simplicity, that the dimension of $Z_{1}$ is one. Other cases can be treated analogously.
It is straightforward to show that this variable marginal effect model can be rewritten as the model in (2) by simply redefining the endogenous variable as $\tilde{X}=\left(X^{\prime}, X^{\prime} Z_{1}\right)^{\prime}$, which has dimension $\tilde{d}=2 d$. Thus, the previous identification results can be readily applied to this case. The relevance condition becomes

$$
E\left[\delta_{\tilde{X}} \delta_{\tilde{X}}^{\prime}\right] \text { is non-singular. }
$$

So, for example, if $Z$ is discrete with $q$ points of support, the rank condition is

$$
\operatorname{rank}\left(\Delta_{\tilde{X}}\right)=2 d,
$$

with an order condition $q \geq 2 d$. More generally, if $\beta_{j}=\gamma_{0 j}+\gamma_{1 j} Z_{1}+\gamma_{2 j} Z_{2}$, with both $Z_{1}$ and $Z_{2}$ univariate, the rank condition becomes

$$
\operatorname{rank}\left(\Delta_{\tilde{X}}\right)=3 d,
$$

where now $\tilde{X}=\left(X^{\prime}, X^{\prime} Z_{1}, X^{\prime} Z_{2}\right)^{\prime}$, and the order condition becomes $q \geq 3 d$. So, for example, in our application where we have $q=6$ and $d=2$ the order condition is satisfied, even when both marginal effects depend on $Z_{1}$ and $Z_{2}$. This means that if the rank condition is satisfied, the $\gamma^{\prime} s$ are identified and we can test hypotheses such as, for example, $H_{0}: \gamma_{11}=0$ or $H_{0}: \gamma_{12}=\gamma_{22}=0$. Next section provides an asymptotically normal estimator for the parameters $\tilde{\beta}=\left(\gamma_{01}, \gamma_{11}, \gamma_{21}, \gamma_{02}, \gamma_{12}, \gamma_{22}\right)^{\prime}$ in this example, or more generally, for $\beta_{0}$ in model (2), which allows researchers to draw inferences on multiple marginal effects in RDD.

## 3 Estimation

Our identification strategy builds on the equation

$$
\begin{equation*}
E\left[Y_{i} \mid Z_{i}, W_{i}=w\right]=\beta^{\prime}(w) E\left[X_{i} \mid Z_{i}, W_{i}=w\right]+E\left[H_{i} \mid Z_{i}, W_{i}=w\right], \tag{6}
\end{equation*}
$$

by exploiting the discontinuity in $E\left[X_{i} \mid Z_{i}, W_{i}=w\right]$ and the continuity of $\beta(w)$ and $E\left[H_{i} \mid Z_{i}, W_{i}=w\right]$ at the threshold $w_{0}$, which henceforth is taken as $w_{0}=0$ without loss of generality. Implementing this identification strategy requires to fit a model for $E\left[Y_{i} \mid Z_{i}, W_{i}=w\right]$ and $E\left[X_{i} \mid Z_{i}, W_{i}=w\right]$ locally around $w=0$.

Applied researchers of the RDD methodology often fit locally a reduced form model of the form

$$
Y_{i}=\alpha_{y}+\pi_{y} D_{i}+g^{y}\left(W_{i}\right)+\gamma_{y}^{\prime} Z_{i}+v_{i}^{y},
$$

where $D_{i}=1\left(W_{i} \geq 0\right), g^{y}(w)$ is a smooth function of $w$, and $v_{i}^{y}$ is an error term. Then, they proceed by specifying a similar first stage for the univariate treatment variable $X_{i}$,

$$
\begin{equation*}
X_{i}=\alpha_{x}+\pi_{x} D_{i}+g^{x}\left(W_{i}\right)+\gamma_{x}^{\prime} Z_{i}+v_{i}^{x} \tag{7}
\end{equation*}
$$

and estimating these two equations by Ordinary Least Squares (OLS). Equivalently, they estimate the parameter $\beta_{y}=\pi_{y} / \pi_{x}$ by Two Stage Least Squares (TSLS) using $D_{i}$ as an instrument for $X_{i}$, and treating the smooth function of $W_{i}$ and $Z_{i}$ as the non-excluded exogenous variables. This method does not exploit variability of the first stages in covariates, provides just-identification only when $\pi_{x}$ is not zero, and does not allow for multivariate treatment variables. We follow our identification strategy above to propose an estimator that overcomes these limitations by exploiting heterogeneity in the first stages in covariates, while allowing for multiple treatments.

We will exploit the variability of the first stages in covariates, but a fully nonparametric estimator of (6) would be affected by the so-called "curse of dimensionality" when $Z_{i}$ is high dimensional and/or sample sizes are moderate or small. To address the "curse of dimensionality" problem of fully nonparametric methods, while allowing for heterogeneity in covariates, this article proposes a semiparametric varying coefficient specification of the first stage

$$
\begin{equation*}
X_{i}=\alpha_{0 X}\left(W_{i}\right)+\alpha_{1 X}\left(W_{i}\right) Z_{i}+\varepsilon_{i}^{x} \tag{8}
\end{equation*}
$$

where $\alpha_{0 X}(\cdot)$ and $\alpha_{1 X}(\cdot)$ are unknown functions of $W$ and $\varepsilon_{i}^{x}$ is a prediction error term. This semiparametric specification avoids smoothing in the possibly high dimensional $Z$, so only smoothing in the one dimensional running variable $W$ is involved.

We could estimate $\alpha_{0 X}(w)$ and $\alpha_{1 X}(w)$ locally at $w=0$ by a constant kernel method. However, it is well known that the local constant kernel estimator has generally worse bias properties than the local linear kernel estimator at discontinuity points; see Fan and Gijbels (1996). For this reason, we suggest implementing our identification strategy for the RDD with a local linear estimator. This corresponds to the use of linear (as opposed to just constant) approximations for $\alpha_{0 X}(\cdot)$ and $\alpha_{1 X}(\cdot)$ around each side of the threshold $w_{0}=0$. Intuitively, this means we approximate the first stage by

$$
\begin{align*}
X_{i} & \approx \alpha_{0 X}^{+} D_{i}+\alpha_{1 X}^{+} Z_{i} D_{i}+\dot{\alpha}_{0 X}^{+} W_{i} D_{i}+\dot{\alpha}_{1 X}^{+} Z_{i} W_{i} D_{i}  \tag{9}\\
& +\alpha_{0 X}^{-}\left(1-D_{i}\right)+\alpha_{1 X}^{-} Z_{i}\left(1-D_{i}\right)+\dot{\alpha}_{0 X}^{-} W_{i}\left(1-D_{i}\right)+\dot{\alpha}_{1 X}^{-} Z_{i} W_{i}\left(1-D_{i}\right)+\varepsilon_{i}^{x} \\
& =\alpha_{0 X}^{-}+\pi_{0 X} D_{i}+\pi_{1 X} Z_{i} D_{i}+g^{x}\left(W_{i}, Z_{i}\right)+\alpha_{1 X}^{-} Z_{i}+\varepsilon_{i}^{x} \tag{10}
\end{align*}
$$

where $\pi_{0 X}=\alpha_{0 X}^{+}-\alpha_{0 X}^{-}, \pi_{1 X}=\alpha_{1 X}^{+}-\alpha_{1 X}^{-}$and $g^{x}\left(W_{i}, Z_{i}\right)=\dot{\alpha}_{0 X}^{+} W_{i} D_{i}+\dot{\alpha}_{1 X}^{+} Z_{i} W_{i} D_{i}+\dot{\alpha}_{0 X}^{-} W_{i}(1-$ $\left.D_{i}\right)+\dot{\alpha}_{1 X}^{-} Z_{i} W_{i}\left(1-D_{i}\right)$. Comparing (7) and (10) we see that exploiting heterogeneity in the first stages permits the use of additional instruments, namely $Z_{i} D_{i}$, for estimating the marginal effects.

Define $S_{+i}=D_{i} \cdot\left(1, W_{i}, Z_{i}, Z_{i} W_{i}\right)^{\prime}, S_{-i}=\left(1-D_{i}\right) \cdot\left(1, W_{i}, Z_{i}, Z_{i} W_{i}\right)^{\prime}$, and $S_{i}=\left(S_{+i}^{\prime}, S_{-i}^{\prime}\right)^{\prime}$. We formalize our approach as a TSLS which solves the first stage problem in (10)

$$
\widehat{\alpha}_{X}=\arg \min _{a} \sum_{i=1}^{n}\left|X_{i}-S_{i}^{\prime} a\right|^{2} k_{h_{n}}\left(W_{i}\right)
$$

where $k_{h_{n}}(W)=k\left(W / h_{n}\right), k$ is a kernel function and $h_{n}$ is a bandwidth parameter satisfying some standard conditions in Section B in the Appendix. Then, in the second stage, we run a local linear regression $Y_{i}$ on $\hat{X}_{i}=S_{i}^{\prime} \widehat{\alpha}_{X}$ and $C_{i}=\left(1, Z_{i}, W_{i}, D_{i} \cdot W_{i}, Z_{i} \cdot W_{i}, Z_{i} \cdot D_{i} \cdot W_{i}\right)^{\prime}$, i.e.

$$
\left[\begin{array}{l}
\hat{\beta} \\
\hat{\eta}
\end{array}\right]=\arg \min _{\beta, \eta} \sum_{i=1}^{n}\left(Y_{i}-\beta^{\prime} \hat{X}_{i}-\eta^{\prime} C_{i}\right)^{2} k_{h_{n}}\left(W_{i}\right) .
$$

Note that $C_{i}$ contains the set of non-excluded "exogenous" variables in our approach, cf. (10).
The following result establishes the asymptotic normality of the proposed TSLS. Its proof and its regularity conditions are given in the Appendix Section B.

Theorem 3.1 Let Assumption 1 and Assumption 2 hold. Let also Assumption 4 in Section B in the Appendix hold. Then

$$
\sqrt{n h_{n}}\left(\hat{\beta}-\beta_{0}\right) \rightarrow_{d} N(0, \Sigma)
$$

where $\Sigma$ is given in Section B in the Appendix.

### 3.1 Implementation

For implementing our estimator we recommend using the uniform kernel

$$
\begin{equation*}
k_{h_{n} i}=1\left(-h_{n} \leq W_{i} \leq h_{n}\right) . \tag{11}
\end{equation*}
$$

This means the estimator can be easily implemented by restricting the sample $\left\{\left(Y_{i}, X_{i}, Z_{i}, W_{i}\right)\right\}_{i=1}^{n}$ to only those observations such that $-h_{n} \leq W_{i} \leq h_{n}$, and running a TSLS regression of $Y_{i}$ onto $X_{i}$ and $C_{i}$, treating $C_{i}$ as exogenous, and using $\left(D_{i}, Z_{i} \cdot D_{i}\right)^{\prime}$ as a vector of "instruments" for $X_{i}$. When $X$ is $d$-dimensional and $Z$ is $p$-dimensional, the necessary order condition is $p \geq d$. We recommend running the first stage and checking for heterogeneity in covariates by means of visual checks and formal tests of significance. Similarly, we also recommend checking for variable marginal effects as a robustness check.

The asymptotic variance of $\hat{\beta}$ can be consistently estimated by the standard TSLS asymptotic variance. Implementation of $\hat{\beta}$ requires the choice of a bandwidth parameter $h_{n}$. We can choose $h_{n}$ along the lines suggested in Calonico, Cattaneo and Titiunik (2014), which can be adapted to the presence of covariates as shown in Calonico, Cattaneo, Farrell and Titiunik (2016). Nevertheless, we have found in all our numerical examples as well as the application that our estimator is not sensitive to the bandwidth parameter, an in particular, it is far less sensitive than standard RDD estimators. See Figure 1 for empirical evidence supporting this claim. In our numerical examples we have found that the simple rule $h_{n}=2 n^{-1 / 4}$ performs well. Nevertheless, we recommend sensitivity analysis by varying the bandwidth, see our application for illustration.

Note that the way in which we introduce covariates in our RDD approach is different from how is traditionally done in RDD; see, e.g., Imbens and Lemieux (2008). The traditional RDD with covariates is a TSLS with exogenous variables $C_{i}^{R D D}=\left(1, Z_{i}, W_{i}, D_{i} \cdot W_{i}\right)^{\prime}$ and a single excluded instrument $D_{i}$ for $X_{i}$. Our semiparametric varying coefficient specification accounts for the additional exogenous variables $Z_{i} \cdot W_{i}$ and $Z_{i} \cdot D_{i} \cdot W_{i}$, while the interaction term $Z_{i} \cdot D_{i}$ is used as an additional instrument to help identify multiple effects in our setting.

## 4 Monte Carlo Simulations

This section studies the finite sample performance of the proposed estimator, in comparison with standard RDD estimators when possible. The first Data Generating Process (DGP) is used to illustrate the finite sample performance of the proposed RDD estimator in the context of the single treatment variable. The data is generated according to:

$$
\begin{aligned}
& Y=\alpha+\beta X+\gamma Z+u, \\
& D=1(W \geq 0) \\
& X=\alpha_{0}+\alpha_{1} D+\alpha_{2} Z+\alpha_{3} D \cdot Z+\varepsilon_{X},
\end{aligned}
$$

where $\left(u, \varepsilon_{X}, W, Z\right)$ are independent and identically distributed as standard normals. Note that with this design

$$
\lim _{w \downarrow 0} E[X \mid W=w, Z]=\alpha_{0}+\alpha_{1}+\left(\alpha_{2}+\alpha_{3}\right) Z
$$

and

$$
\lim _{w \uparrow 0} E[X \mid W=w, Z]=\alpha_{0}+\alpha_{2} Z .
$$

Therefore, $\delta_{X}=\alpha_{1}+\alpha_{3} Z$. On the other hand, since $E[Z \mid W]=0$,

$$
\lim _{w \downarrow 0} E[X \mid W=w]=\alpha_{0}+\alpha_{1}
$$

and

$$
\lim _{w \uparrow 0} E[X \mid W=w]=\alpha_{0} .
$$

If we define, for a generic $V$,

$$
\delta_{V}^{R D D}=\lim _{w \downarrow \bar{w}} E[V \mid W=w]-\lim _{w \uparrow \bar{w}} E[V \mid W=w],
$$

then $\delta_{X}^{R D D}=\alpha_{1}$ controls the level of identification of the standard RDD, whereas $\alpha_{1}$ and $\alpha_{3}$ simultaneously control the level of identification for the over-identified RDD estimator. We compare the standard RDD estimator ( $\widehat{\beta}_{R D D}$ ), the standard RDD estimator with covariates ( $\widehat{\beta}_{R D D \operatorname{cov}}$ ), and the over-identified $\operatorname{RDD}$ estimator $(\hat{\beta})$. We consider the parameter values $(\alpha, \beta, \gamma)=(0,1,0),\left(\alpha_{0}, \alpha_{2}, \alpha_{3}\right)=(0,1,1)$ and several values of $\alpha_{1}$. We implement all estimators as in Section 3 with a uniform kernel (11) and a bandwidth $h_{n}=2 n^{-1 / 4}$.

Table 1 reports the average bias and MSE based on 10000 Monte Carlo simulations. For $\alpha_{1}=0$, the standard RDD is not able to identify the parameter $\beta$, and, as expected, has a MSE that remains large for large $n$. Adding covariates in the standard RDD improves slightly the bias and the MSE for moderate and large samples, but yet does not identify the parameter and leads to large MSE when $\alpha_{1}=0$. In contrast, our estimator $\hat{\beta}$ presents a satisfactory performance, with small MSEs that decrease with the sample size. It is surprising that for $\alpha_{1}=1$ the MSEs for standard RDD, with or without

Table 1: Average Bias and MSE: RDD

| $\alpha_{1}$ | $n$ | Bias |  |  | MSE |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | $\widehat{\beta}_{R D D}$ | $\widehat{\beta}_{R D D \operatorname{cov}}$ | $\widehat{\beta}$ | $\widehat{\beta}_{R D D}$ | $\widehat{\beta}_{R D D c o v}$ | $\widehat{\beta}$ |
| 0 | 100 | 0.233 | 2.173 | -0.014 | 1,546.280 | 24,082.300 | 3.167 |

|  | 500 | -0.001 | -0.001 | -0.000 | 0.184 | 0.030 | 0.022 |
|  | 1000 | 0.003 | 0.003 | 0.002 | 0.017 | 0.015 | 0.012 |

Note: 10,000 Monte Carlo Simulations. Numbers are rounded to the nearest milesimal. When there is a "-" sign in front of a 0.000 it means that the number is between -0.0005 and 0 .
covariates, remain relative large even for large sample sizes as $n=1000$. This seems to be a case of weak identification by standard RDD, see Feir, Lemieux and Marmer (2016). Indeed, it requires a value of $\alpha_{1}=2$ and a sample size of $n \geq 500$ for the standard RDD to achieve comparable results to those of our estimator.

Next, we study the sensitivity of the proposed estimator to the bandwidth parameter. Figure 1 reports the MSE for this DGP in the "weakly" and "strongly" identified cases (i.e., when $\alpha_{1}=1$ and $\alpha_{1}=2$ ) for sample sizes 300 and 1,000 , and where the bandwidth is chosen as $h_{n}=c n^{-1 / 4}$ for a constant $c=1,1.25,1.5, \ldots, 5$. Note that the vertical scale of the plots is different, since the disparities between the standard RDD and our method can sometimes be extreme.

The results show that RDD without covariates is particularly sensitive to the choice of the bandwidth. Including covariates helps significantly, but still leads to variable results, particularly for low values of the bandwidth. Our estimator has the smallest MSEs, uniformly over all values of the bandwidth (never above 0.02), and a MSE that is flatter as a function of the bandwidth. These conclusions hold even in the strongly identified case where $\alpha_{1}=2$. This DGP illustrates the potential benefits of our approach even in situations where the standard RDD is applicable.

Figure 1: Sensitivity to the Choice of Bandwidth

Note: Horizontal axis shows the values of $c=1,1.25,1.5,1.75, \ldots$, reflecting different bandwidths: $h_{n}=c n^{-1 / 4}$. Vertical axis shows the MSE, with different scales depending on the figure. When a curve is only shown for high values of $c$ it is because the values are off the scale for the lower values of $c$. For example, in Figure 1a the MSE of the standard RDD for $c<3.25$ is over 80 .

We also consider a second DGP with two treatments:

$$
\begin{aligned}
Y & =\alpha+\beta_{1} X_{1}+\beta_{2} X_{2}+\gamma Z+u \\
D & =1(W \geq 0) \\
X_{1} & =\alpha_{01}+\alpha_{11} D+\alpha_{21} Z+\alpha_{31} D \times Z+\varepsilon_{1} \\
X_{2} & =\alpha_{02}+\alpha_{12} D+\alpha_{22} Z+\alpha_{32} D \times Z+\varepsilon_{2}
\end{aligned}
$$

where $\left(u, W, \varepsilon_{1}, \varepsilon_{2}\right)$ are independent normal random variables with variances $0.25,0.25,1$ and 1 , respectively. In this model $\delta_{Y}=\beta_{1} \delta_{X_{1}}+\beta_{2} \delta_{X_{2}}$ with

$$
\delta_{X_{1}}=\alpha_{11}+\alpha_{31} Z \text { and } \delta_{X_{2}}=\alpha_{12}+\alpha_{32} Z .
$$

Thus, our relevance condition is satisfied as long as

$$
\operatorname{det}\left|\begin{array}{ll}
\alpha_{11} & \alpha_{31}  \tag{12}\\
\alpha_{12} & \alpha_{32}
\end{array}\right| \neq 0
$$

The parameters in the structural equation are set at $\alpha=0, \beta_{1}=1, \beta_{2}=2$ and $\gamma=0$. We also set $\alpha_{01}=\alpha_{02}=\alpha_{21}=\alpha_{22}=0$. The results reported below are not sensitive to these parameter values. More critical are the values for $\left(\alpha_{11}, \alpha_{31}, \alpha_{12}, \alpha_{32}\right)$, which determine the rank condition. We consider three different cases: (i) Case 1: $\alpha_{11}=2, \alpha_{31}=1, \alpha_{12}=0, \alpha_{32}=1$; (ii) Case 2: $\alpha_{11}=0, \alpha_{31}=$ $-2, \alpha_{12}=2, \alpha_{32}=1$; and (iii) Case 3: $\alpha_{11}=-2, \alpha_{31}=2, \alpha_{12}=1, \alpha_{32}=1$. All the three cases satisfy the relevance condition (12). In contrast, the identifying condition for standard RDD varies according to the case considered, since

$$
\begin{aligned}
\delta_{Y}^{R D D} & =\beta_{1} \delta_{X_{1}}^{R D D}+\beta_{2} \delta_{X_{2}}^{R D D} \\
& =\beta_{1} \alpha_{11}+\beta_{2} \alpha_{12} .
\end{aligned}
$$

Thus, in Case 1, $\alpha_{12}=0$ and $\operatorname{RDD}$ identifies $\beta_{1}$, although it fails to identify $\beta_{2}$; in Case $2, \alpha_{11}=0$ and $\operatorname{RDD}$ identifies $\beta_{2}$, although it fails to identify $\beta_{1}$; and in the mixed case of Case 3 neither $\beta_{1}$ nor $\beta_{2}$ are identified by standard RDD methods. We implement the standard RDD estimator and the standard RDD estimator with covariates for each treatment separately, and compare these estimates with the over-identified RDD estimator. Table 2 provides the average bias and MSE for $\beta_{1}$ and $\beta_{2}$ based on 10,000 Monte Carlo simulations, and sample sizes $n=300,500,1000$ and 5000 . We implement all estimators as in Section 3 with a uniform kernel (equation (11)) and bandwidth $h_{n}=2 n^{-1 / 4}$.

Table 2: Average Bias and MSE

|  | 5000 | -74.3120 | 7.4588 | 0.0000 | $\infty$ | $\infty$ | 0.0007 | 0.0029 | 0.0015 | -0.0000 | 0.0072 | 0.0050 | 0.0006 |
|  | 300 | 0.5730 | 0.5366 | -0.0003 | 1.6836 | 0.3550 | 0.0027 | -2.4689 | -2.1373 | 0.0009 | 20.5520 | 180.2900 | 0.0118 |
| 3 | 500 | 0.5393 | 0.5232 | 0.0003 | 0.3507 | 0.3095 | 0.0017 | -2.2625 | -2.1766 | -0.0003 | 7.0904 | 5.6605 | 0.0073 |
| 3 | 1000 | $0.5201$ | 0.5126 | 0.0003 | 0.3001 | 0.2834 | 0.0010 | -2.1365 | -2.1005 | 0.0005 | 5.1558 | 4.7913 | 0.0040 |
|  | 5000 | 0.5046 | 0.5028 | -0.0000 | 0.2622 | 0.2582 | 0.0003 | -2.0379 | -2.0277 | -0.0001 | 4.2752 | 4.1951 | 0.0011 |

Note: 10000 Monte Carlo Simulations. Columns 3-5 show the bias of the estimation of $\beta_{1}$ using the standard RDD, the standard RDD with covariates, and our method respectively. The remaining columns are analogous.

Table 2 shows that the standard RDD has a satisfactory performance in estimating $\beta_{1}$ in Case 1 , where it identifies, but also illustrates its inconsistency in estimating $\beta_{1}$ in Case 2 in and Case 3 . The behavior of the standard RDD in identifying $\beta_{2}$ is analogous, only it performs satisfactorily in Case 2 , where it identifies, but it is inconsistent in both Case 1 and Case 3. The standard RDD is particularly unreliable for the extreme Cases 1 and 2 when it does not identify ( $\beta_{2}$ in Case 1 and $\beta_{1}$ in Case 2). For the mixed case, standard RDD is more stable in estimating both coefficients, but its bias and MSE do not converge to zero as the sample size increases. All of this is true even when covariates are included. In contrast, our approach ( $\hat{\beta}_{1}$ and $\hat{\beta}_{2}$ ) performs uniformly well across the three cases considered, and outperforms the standard RDD even in the case where RDD identifies the parameter.

Overall, these Monte Carlo results provide supporting evidence of the robustness of our identification strategy in the case of a single treatment and its ability to identify multiple treatment effects in situations where the standard RDD fails.

## 5 An Application to the Estimation of the Effect of Insurance Coverage on Health Care Utilization

We apply our approach to the problem of estimating the effects of insurance coverage on health care utilization with a regression discontinuity design, as in Card, Dobkin and Maestas (2008). They exploit the fact that Medicare eligibility varies discontinuously at age 65 . Medicare eligibility may affect health care utilization via two channels. First, it provides coverage to people who were previously uninsured. Second, it provides more generous coverage to people who were previously insured by other, less generous insurance policies. Let $Y$ be a measure of health care use (e.g., whether the person did not get care for cost reasons last year). The two main explanatory variables of interest are whether the person has any insurance coverage (i.e., one or more policies) ( $X_{1}$ ), and whether the person has insurance coverage by two or more policies $\left(X_{2}\right)$. The running variable $W$ is defined to be the age (measured in quarters of a year) relative to the threshold of 65 years of age, and the treatment status $D$ is whether the person is eligible to Medicare. We want to identify $\beta_{1}$ and $\beta_{2}$ in the following model:

$$
\begin{equation*}
Y=\alpha+\beta_{1} X_{1}+\beta_{2} X_{2}+\gamma^{\prime} Z+\varepsilon \tag{13}
\end{equation*}
$$

were $Z$ represents the variables which we will explore to generate variation in the first stage (e.g., race, education level).

Table 3 presents the summary statistics for the key variables of our sample, obtained from the National Health Interview Survey (NHIS) from 1999 to 2003. ${ }^{4}$ We consider three different outcome variables $(Y)$ : whether the person delayed care last year for cost reasons, whether the person did not get care last year for cost reasons, and whether the person went to the hospital last year. ${ }^{5}$

[^3]Table 3: Summary Statistics

| Variable | All | Non-Hispanic White |  |  | Minority |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

|  | $(0.49)$ | $(0.50)$ | $(0.50)$ | $(0.48)$ | $(0.50)$ | $(0.48)$ | $(0.47)$ |
| Observations | 63,165 | 8,337 | 16,037 | 21,352 | 8,293 | 4,302 | 4,844 |

Note: Source: NHIS 1999-2003. Standard deviations in parentheses. "HS Dropout" represents people who have less than a high school degree. "HS Graduate" represents those who have a high school degree. " $>$ HS Graduate" represents those who have some college or more.

The table shows that non-Hispanic Whites are less likely to delay or ration care because of cost reasons relative to minorities. The results are analogous when comparing people with higher vs. lower education levels. However, people with lower education levels go more often to Hospitals than people with higher education levels, and non-Hispanic Whites go as often as minorities, except for lowly educated ones.

The table also shows that non-Hispanic Whites tend to be insured with a higher likelihood than minorities, and at the same time are more likely to carry more than one insurance policy. Additionally, more educated people are more likely to have some insurance than less educated people, irrespective of the race. However, less educated Whites are more likely to carry two or more insurance policies than their more educated counterparts. This counter-intuitive correlation is better understood in the context of age as an important confounder. As seen in the second to last row of the table, people with higher education levels are less likely to be eligible to Medicare. Indeed, Figure 2 shows that people with lower education levels tend to be older than people with higher education levels, so they are more likely to be eligible to Medicare. Following Card, Dobkin and Maestas (2008), we use a regression discontinuity design to circumvent this and other endogeneity concerns. ${ }^{6}$

[^4]Figure 2: Age Distribution by Level of Education

Note: For each education level, this Figure shows the Kernel density plot of the age distribution (measured in quarters of a year). Kernel: Epanechnikov. Bandwidth: 1.

To see how an RDD is reasonable in this context, Figure 3 shows plots suggestive that people just younger and just older than 65 years of age are comparable in terms of race and education. Overall, we find no evidence of discontinuity at 65 years of age for a wide range of covariates, suggesting that variables included in $Z$ are likely exogenous conditional on being close enough to the threshold of 65 years of age.

Figure 3: Validity Plots

Note: The scatter plot shows the average of the variable described in the vertical axis for each age level (measured in quarters of a year).

Figure 4 shows the first stage discontinuity plots for different subgroups of people based on race should also affect $Y$ directly, as for example the person's income (see Section II.A in Card, Dobkin and Maestas (2008) for other potential confounders in this context.) An RDD approach aims at avoiding all such confounders.
and education. While the discontinuity in $X_{1}$ (Panel (a)) is larger for Minorities with low levels of education, the discontinuity in $X_{2}$ (Panel (b)) is larger for Whites with high levels of education. These results suggest that eligibility to Medicare affects the insurance policies that people carry differently depending on their socio-economic status.

## Figure 4: First Stage By Race and Education

Note: The scatter plot shows the average of the variable described in the vertical axis for each age level (measured in quarters of a year) and for each subsample represented in the legend.

Table 4 shows the intention to treat or "reduced-form" estimates obtained from a local linear regression using a standard RD design. ${ }^{7}$ As expected, results differ by race and education level. While minorities with lower levels of education tend to benefit from eligibility by discontinuously not delaying and not rationing care for cost reasons, Whites with higher levels of education tend to benefit from eligibility by discontinuously going more to hospitals. As discussed in Card, Dobkin and Maestas (2008), the heterogeneous results found in both the first stage and the intention to treat estimates suggest that perhaps Medicare eligibility might be affecting different outcome variables through different channels. Intuitively, insurance coverage ( $X_{1}$ ) might influence health decisions that are more recurrent and less expensive (such as delaying or rationing care) more than insurance generosity $\left(X_{2}\right)$, while the opposite might happen for more expensive and sporadic decisions such as the decision to get hospitalized. Next, we use our approach to make this analysis more formal.

In Table 5, we report the Two Stage Least Square estimates of $\beta_{1}$ and $\beta_{2}$ in equation (13) using different approaches. Column I shows the standard RDD estimate of $\beta_{1}$ under the restriction $\beta_{2}=0$, and column II shows the analogous estimate of $\beta_{2}$ under the restriction $\beta_{1}=0$. Columns III and IV show analogous results to columns I and II using our approach and each of the six combinations of race and education as elements of $Z$. Finally, columns V and VI show joint estimates of $\beta_{1}$ and $\beta_{2}$ using our approach under no restriction in equation (13). The standard RDD univariate estimates suggest

[^5]Table 4: Intention to Treat Results - Standard RD

| $Y$ | h | All | Whites |  |  | Minorities |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Note: This table shows standard "reduced form" or intention to treat estimates of the effect of Medicare eligibility on $Y$ for the whole sample and for subsamples based on race/ethnicity and education. These were obtained from a local linear regression with rectangular kernel and bandwidth $h$ as described in the second column of the table. Standard errors clustered by values of the running variable $W$ are shown in parentheses.
no pattern similar to the intuition discussed above. Based on these results, one would conclude that $X_{1}$ or $X_{2}$ affecting $Y$ are similarly plausible interpretations irrespective of $Y$. The reason for this is that the standard RDD is not exploiting the over-identifying restrictions which are generated by the heterogeneity in the first stage by values of $Z$, as we exploit in our approach. Our approach in the univariate version, which exploits the heterogeneity in the first stage but does not add both $X_{1}$ and $X_{2}$ in the same regression, makes this pattern sharper: while we find that $\beta_{1}$ is significant mostly for "Delayed Care" and "Rationed Care", we find that $\beta_{2}$ is significant mostly for "Hospital Stay".

One important concern with the univariate approaches is that we would be allowing for Medicare eligibility to affect $Y$ only through $X_{1}$ in columns I and III of the table or only through $X_{2}$ in columns II and IV of the table. This could in principle substantially bias the estimates, in case the restrictions $\beta_{2}=0$ (columns I and III) and $\beta_{1}=0$ (columns II and IV) happen to be invalid. In columns V and VI, we present our approach in a multivariate setting in order to avoid making these exclusion restrictions. As expected, the multivariate estimates suggest an even sharper pattern than the results of our approach in the univariate setting: (a) insurance coverage ( $X_{1}$ ) reduces the probability of delaying care for cost reasons, or rationing care for cost reasons, in about 15 to 20 percentage points, depending on the bandwidth, but seem to have no effect on hospital stays; (b) having a second, more generous insurance $\left(X_{2}\right)$ increases the probability of hospital stays in about 5 percentage points, but seems to have no effect on delaying or rationing care for cost reasons.

It is interesting to note that the univariate approaches perform better when the underlying restrictions are plausible, according to our multivariate approach. To see this, consider the results from our multivariate approach (columns (V) and (VI)). They suggest that it is plausible to assume that $\beta_{2}=0$ for the first two outcome variables in the table (Delayed and Rationed Care) and that $\beta_{1}=0$ for the last outcome variable in the table (Went to Hospital). They also suggest that it is not plausible to assume that $\beta_{2}=0$ in the last outcome variable in the table and that $\beta_{1}=0$ in the first two outcome variables in the table. Accordingly, univariate estimates are more similar to the corresponding estimate from the multivariate approach when the underlying restriction is plausible, and more different when the underlying restriction is not plausible (e.g., $\hat{\beta}_{1}$ estimates are more similar across the three methods in the first two outcome variables - when $\beta_{2}=0$ is plausible - than in the last outcome variable - when $\beta_{2}=0$ is not plausible.) Moreover, irrespective of the plausibility of the restriction, the estimates of our univariate approach are closer to the estimates of our multivariate approach than the standard RDD estimates are to our multivariate approach. Intuitively, this happens because our univariate approach exploits the heterogeneity in the first stage while the standard RDD does not.

Finally, we provide some evidence in favor of our key assumption that the parameters of interest ( $\beta_{1}$ and $\beta_{2}$ in equation (13)) do not vary with race or education. As discussed in Section 2.3, we can relax this assumption by allowing for heterogeneity in covariates. In Table 6, we allow for heterogeneity along one of these two dimensions (race, education) at a time, and we perform F-tests for whether the parameters are the same for all levels of race (odd columns) or education (even columns). For comparison, we show results of an analogous test for whether the parameters of the first stage regression of $X_{1}$ or $X_{2}$ are the same for all levels of race and education. Perhaps with the exception of heterogeneity

Note: This table shows 2SLS estimates of the effect of (a) $X_{1}$ (columns I and III) or (b) $X_{2}$ (columns II and IV), or (c) both $X_{1}$ and $X_{2}$ (columns V and VI ) on $Y$ using different approaches. In the univariate case, each column refers to estimates obtained from a different regression, while in the multivariate case both columns refer to estimates obtained from the same regression. These estimates were obtained from a local linear regression with rectangular kernel and bandwidth $h$. Standard errors clustered by values of the running variable $W$ are shown in parentheses.
by race for the outcome variable rationed care, all results point to homogeneity of $\beta_{1}$ and $\beta_{2}$. In all cases, the evidence of heterogeneity in the first stage is overwhelming relative to any evidence of heterogeneity in the structural equation. Taken together, the results suggest that the main idea of exploiting heterogeneity in the first stage effects along these two dimensions while maintaining the assumption of homogeneity in the main effects of interest along these same dimensions fits this application well.

Table 6: Testing for Heterogeneity

| $Z_{1}$ | $h$ | Delayed |  | Rationed |  | Went to Hospital |  | First Stage |  |

|  |  | (0.47) | (0.18) | (0.33) | $(0.23)$ | (0.70) | $(0.69)$ | (0.00) | (0.00) |

Note: This table shows for each bandwidth $h$ the F-test along with corresponding pvalue of the test for whether all elements of the $\beta_{1}$ (odd columns) or $\beta_{2}$ (even columns) are equal to each other. Each panel allows for unrestricted heterogeneity of $\beta_{1}$ and $\beta_{2}$ for each different value of the variable $Z_{1}$, referenced in the first column of the table. For comparison, the last two columns show an analogous test about the 6 coefficients of the first stage (defined by all combinations of race and education).

Overall, our results corroborate in a sharper way the intuition suggested by Card, Dobkin and

Maestas (2008) that Medicare eligibility has generated different effects on health behavior depending on whether the person would otherwise have no insurance, or would otherwise have some insurance, albeit a less generous one.

## 6 Conclusions

This article has proposed a new identification and estimation strategy for RDD. It explores the heterogeneity in the "first stage" discontinuities for different values of a covariate to generate over-identifying restrictions. This allows us to identify quantities which cannot be identified with the standard RDD method, including the effects of multiple endogenous variables, multiple marginal effects of a multivalued endogenous variable, and heterogeneous effects conditional on covariates. For a linear model with a single endogenous variable, when both standard RDD and our approach are applicable, our method yields smaller MSE that are less sensitive to bandwidths than standard RDD procedures.

For multivalued treatments none of the existing RDD procedures identify the marginal effects. We have provided a method that achieves identification in a variety of situations, including situations with variable marginal effects. We have proposed a simple TSLS estimator implementing our identification strategy. Monte Carlo simulations confirm its excellent finite sample performance relative to standard RDD estimators, and the empirical application to health utilization shows its ability to identify multiple marginal effects in a situation of practical interest.

Section A in the Appendix generalizes the identification result to nonparametric variable marginal effects. It should be possible to extend our TSLS procedure to nonparametric cases by using, for example, sieve methods or local polynomial methods. Similarly, nonparametric tests of homogeneous effects could be developed based on these nonparametric estimators. These methods would certainly require larger sample sizes to achieve a similar level of precision to those developed in the paper. Furthermore, these would involve the choice of additional bandwidth parameters. Similarly, it is possible to extend our identification result to the nonparametric continuous treatment case. This would entail a new completeness condition between the continuous treatment and the vector of covariates, similar to the covariance completeness condition studied in Caetano and Escanciano (2017).

The proposed methods enable researchers to estimate multiple marginal effects in situations that inherently have limited exogenous variation. We have shown how covariates bring new possibilities that were currently unexploited. We hope this research will foster a deeper understanding of the effects of policies on economic outcomes and a more efficient use of the data, in particular, covariates.

## A Appendix A: A General Identification Result

This section establishes an identification result that includes the identification result in the main text as a special case. This section also contains proofs for these identification results. Set $Z=\left(Z_{1}, Z_{2}\right)$, where $Z_{1}$ and $Z_{2}$ have dimensions $q_{1}$ and $q_{2}$, respectively (we allow for the possibility of $q_{1}=0$, meaning
$Z_{1}$ is empty). We consider the following generalization of model (1)

$$
\begin{equation*}
Y_{i}=g\left(T_{i}, Z_{1 i}, W_{i}\right)+h\left(Z_{i}, W_{i}, \varepsilon_{i}\right), \tag{14}
\end{equation*}
$$

where now the unknown function $g$ depends on $Z_{1 i}$ in addition to the dependence on the multivalued treatment variable $T_{i}$ and $W_{i}$. Arguing as in the main text, we can write (14) as the varying coefficients model

$$
\begin{equation*}
Y_{i}=\beta\left(Z_{1 i}, W_{i}\right)^{\prime} X_{i}+H_{i}, \tag{15}
\end{equation*}
$$

where $H_{i}=g\left(t_{0}, Z_{1 i}, W_{i}\right)+h\left(Z_{i}, W_{i}, \varepsilon_{i}\right)$, and now the marginal effects depend on $Z_{1 i}$ and $W_{i}$,

$$
\beta\left(Z_{1 i}, W_{i}\right)=\left(g\left(t_{1}, Z_{1 i}, W_{i}\right)-g\left(t_{0}, Z_{1 i}, W_{i}\right), \ldots, g\left(t_{d}, Z_{1 i}, W_{i}\right)-g\left(t_{d-1}, Z_{1 i}, W_{i}\right)\right)^{\prime} .
$$

The following condition generalizes the relevance condition (2).
Assumption $3 E\left[\delta_{X} \delta_{X}^{\prime} \mid Z_{1}\right]$ is positive definite a.s.
Theorem A. 1 Let (14) and Assumption 1 hold. Then, $\beta_{0}\left(z_{1}\right) \equiv \beta\left(z_{1}, w_{0}\right)$ is identified if and only if Assumption 3 holds.

Proof. We first prove the "if" part. Taking limits as in the main text we obtain the equation

$$
\delta_{Y}(Z)=\delta_{X}^{\prime}(Z) \beta_{0}\left(Z_{1}\right) .
$$

Multiplying by $\delta_{X}(Z)$ both sides, and taking conditional means on $Z_{1}$, we arrive at

$$
E\left[\delta_{X}(Z) \delta_{Y}(Z) \mid Z_{1}\right]=E\left[\delta_{X}(Z) \delta_{X}^{\prime}(Z) \mid Z_{1}\right] \beta_{0}\left(Z_{1}\right)
$$

This and the generalized relevance condition yield identification, i.e.

$$
\beta_{0}(Z)=\left(E\left[\delta_{X}(Z) \delta_{X}^{\prime}(Z) \mid Z_{1}\right]\right)^{-1} E\left[\delta_{X}(Z) \delta_{Y}(Z) \mid Z_{1}\right] .
$$

For the necessity part, we suppose the generalized relevance condition does not hold. This means there exists a non-trivial measurable function $\lambda\left(Z_{1}\right)$ such that, a.s.,

$$
\lambda\left(Z_{1}\right)^{\prime} E\left[\delta_{X}(Z) \delta_{X}^{\prime}(Z) \mid Z_{1}\right] \lambda\left(Z_{1}\right)=0 .
$$

Hence,

$$
E\left[\left(\lambda\left(Z_{1}\right)^{\prime} \delta_{X}(Z)\right)^{2}\right]=0,
$$

and thus

$$
\begin{equation*}
\lambda\left(Z_{1}\right)^{\prime} \delta_{X}(Z)=0 \text { a.s. } \tag{16}
\end{equation*}
$$

Let $\beta_{0}\left(Z_{1}\right)$ denote the true value that generated the data, and define $\tilde{\beta}\left(Z_{1}\right)=\beta_{0}\left(Z_{1}\right)+\lambda\left(Z_{1}\right)$ and $\tilde{H}_{i}=H_{i}-\lambda^{\prime}\left(Z_{1 i}\right) X_{i}$. Note that if $H_{i}$ satisfies Assumption 1, $\tilde{H}_{i}$ also does it because by (16),
$\lim _{w \downarrow w_{0}} E[\tilde{H} \mid W=w, Z]-\lim _{w \uparrow w_{0}} E[\tilde{H} \mid W=w, Z]=\lim _{w \downarrow w_{0}} E[H \mid W=w, Z]-\lim _{w \uparrow w_{0}} E[H \mid W=w, Z]-\lambda^{\prime}\left(Z_{1}\right) \delta_{X}(Z)=0$.
Hence, the triple $\left(\alpha(Z), \tilde{\beta}\left(Z_{1}\right), \tilde{H}\right)$ satisfies the same conditions as the triple $\left(\alpha(Z), \beta_{0}(Z), H\right)$, and $\beta_{0}(\cdot)$ is not identified.

Theorem 2.1 is a special case of Theorem A. 1 (the case $q_{1}=0$ ). In this case $Z_{1}$ is empty, $\beta_{0}\left(Z_{1}\right)$ is a constant and

$$
E\left[\delta_{X}(Z) \delta_{X}^{\prime}(Z) \mid Z_{1}\right]=E\left[\delta_{X}(Z) \delta_{X}^{\prime}(Z)\right]
$$

Another special case is $q_{2}=0$. In this case $Z=Z_{1}$ and

$$
E\left[\delta_{X}(Z) \delta_{X}^{\prime}(Z) \mid Z_{1}\right]=\delta_{X}(Z) \delta_{X}^{\prime}(Z)
$$

Within this case, there are two separate subcases: (i) $d=1$ and (ii) $d>1$. In (i) the relevance condition holds iff $\delta_{X}(Z) \neq 0$ with positive probability. In (ii), since the rank of $\delta_{X}(Z) \delta_{X}^{\prime}(Z)$ is at most one, the relevance condition fails, and hence by Theorem A.1, identification fails. We summarize this impossibility result in the following corollary.

Corollary A. 1 Let (14) and Assumption 1 hold. Then, if $q_{2}=0$ and $d>1$, nonparametric identification is not possible.

This impossibility result shows that in order to identify variable marginal effects, some semiparametric restriction is needed. One such restriction is $q_{2}>0$. To better explain the meaning of the relevance condition in the $q_{2}>0$ case, suppose $Z_{j}$ is discrete with support $\left\{z_{j 1}, \ldots, z_{j m_{j}}\right\}$, for $j=1,2$. For each $b$ fixed, $1 \leq b \leq m_{1}$, define the $m_{2} \times d$ matrix $\Delta_{b}$ with $l$-th row $\delta_{X}\left(z_{1 b}, z_{2 l}\right)$, for $1 \leq l \leq m_{2}$. Then, the relevance condition holds, iff for all $b, 1 \leq b \leq m_{1}$,

$$
\operatorname{rank}\left(\Delta_{b}\right)=d
$$

This requires the order condition $m_{2} \geq d$.

## B Appendix: Proof of Asymptotic Results

In this section we establish the asymptotic normality of the proposed estimator $\hat{\beta}$. For simplicity, we consider the case where $X$ and $Z$ are univariate, although the extension to the multivariate case only involves further notation. Without loss of generality assume hereinafter that $w_{0}=0$. We introduce some further notation and assumptions. Let $\varepsilon_{V_{i}}=V_{i}-E\left[V_{i} \mid W_{i}, Z_{i}\right]$ denote the regression errors for $V=Y$ and $V=X$. Define $\varepsilon_{U_{i}}=\varepsilon_{Y_{i}}-\beta_{0} \varepsilon_{X_{i}}$. Assume, for $V=Y$ and $V=X$,

$$
\begin{equation*}
E\left[V_{i} \mid W_{i}, Z_{i}\right]=\alpha_{0 V}\left(W_{i}\right)+\alpha_{1 V}\left(W_{i}\right) Z_{i}, \tag{17}
\end{equation*}
$$

We investigate the asymptotic properties of $\hat{\beta}$ under the following assumptions, which parallel those of Hahn, Todd and van der Klaauw (1990):

## Assumption 4 Suppose that

1. The sample $\left\{\chi_{i}\right\}_{i=1}^{n}$ is an iid sample, where $\chi_{i}=\left(Y_{i}, X_{i}, Z_{i}, W_{i}\right)$.
2. The density of $W$, $f(w)$, is continuous and bounded near $w=0$. It is also bounded away from zero near $w=0 . \Gamma$ defined below is positive definite.
3. The kernel $k$ is continuous, symmetric and nonnegative-valued with compact support.
4. The functions $\mu_{j}(w)=E\left[Z^{j} \mid W=w\right], \mu_{X j}(w)=E\left[Z^{j} X \mid W=w\right], \mu_{Y j}(w)=E\left[Z^{j} Y \mid W=w\right]$, $\sigma_{j}^{2}(w)=E\left[Z_{i}^{2 j} \mid W=w\right], \sigma_{X j}^{2}(w)=E\left[Z_{i}^{2 j} X_{i}^{2} \mid W=w\right], \sigma_{Y j}^{2}(w)=E\left[Z_{i}^{2 j} Y_{i}^{2} \mid W=w\right], q_{j}(w)=$ $E\left[Z^{2 j} \varepsilon_{U_{i}}^{2} \mid W=w\right]$, and $s_{j}(w)=E\left[Z^{3 j} \varepsilon_{U_{i}}^{3} \mid W=w\right]$ are uniformly bounded near $w=0$, with well-defined and finite left and right limits to $w=0$, for $j=0,1$ and 2 .
5. The bandwidth satisfies $n h_{n}^{5} \rightarrow 0$.
6. For $V=Y$ and $V=X$ : (i) let 17 hold; (ii) for $w>0$ or $w<0, \alpha_{0 V}(w)$ and $\alpha_{1 V}(w)$ are twice continuously differentiable; (iii) there exists some $M>0$ such that $\dot{\alpha}_{j V}^{+}(w)=\lim _{u \downarrow w} \partial \alpha_{j V}(u) / \partial u$ and $\ddot{\alpha}_{j V}^{+}(w)=\lim _{u \downarrow w} \partial^{2} \alpha_{j V}(u) / \partial u^{2}$ are uniformly bounded on $(0, M]$, for $j=0,1$. Similarly, $\dot{\alpha}_{j V}^{-}(w)=\lim _{u \uparrow w} \partial \alpha_{j V}(u) / \partial u$ and $\ddot{\alpha}_{j V}^{-}(w)=\lim _{u \uparrow w} \partial^{2} \alpha_{j V}(u) / \partial u^{2}$ are uniformly bounded on $[-M, 0)$, for $j=0,1$.

For a measurable function of the data $g\left(\chi_{i}\right)$, define the local linear sample mean

$$
\hat{E}\left[g\left(\chi_{i}\right)\right]=\frac{1}{n h_{n}} \sum_{i=1}^{n} g\left(\chi_{i}\right) k_{i h_{n}} .
$$

Let $S_{i n}$ and $C_{i n}$ be defined the same as $S_{i}$ and $C_{i}$ but with $W_{i}$ replaced by $W_{i} / h_{n}$. Define $\tilde{X}_{i}=\left(X_{i}, C_{i}^{\prime}\right)^{\prime}$, $\tilde{X}_{\text {in }}=\left(X_{i}, C_{\text {in }}^{\prime}\right)^{\prime}$, and $\theta=\left(\beta_{0}, \eta^{\prime}\right)^{\prime}$, where $\eta=\left(\eta_{1}, \ldots, \eta_{6}\right)^{\prime}$ has the same dimension as $C_{i n}$. Define $\theta_{n}=\left(\beta_{0}, \eta_{1}, \eta_{2}, h_{n} \eta_{3}, h_{n} \eta_{4}, h_{n} \eta_{5}, h_{n} \eta_{6}\right)^{\prime}$. With this notation in place, the TSLS is the first component of

$$
\begin{aligned}
\hat{\theta}_{n} & =\left(\hat{E}\left[\tilde{X}_{i n} S_{i n}^{\prime}\right]\left(\hat{E}\left[S_{i n} S_{i n}^{\prime}\right]\right)^{-1} \hat{E}\left[S_{i n} \tilde{X}_{i n}^{\prime}\right]\right)^{-1} \hat{E}\left[\tilde{X}_{i n} S_{i n}^{\prime}\right]\left(\hat{E}\left[S_{i n} S_{i n}^{\prime}\right]\right)^{-1} \hat{E}\left[S_{i n} Y_{i}\right] \\
& =\theta_{n}+\left(\hat{E}\left[\tilde{X}_{i n} S_{i n}^{\prime}\right]\left(\hat{E}\left[S_{i n} S_{i n}^{\prime}\right]\right)^{-1} \hat{E}\left[S_{i n} \tilde{X}_{i n}\right]\right)^{-1} \hat{E}\left[\tilde{X}_{i n} S_{i n}^{\prime}\right]\left(\hat{E}\left[S_{i n} S_{i n}^{\prime}\right]\right)^{-1} \hat{E}\left[S_{i n} U_{i}\right],
\end{aligned}
$$

where $U_{i}=Y_{i}-\tilde{X}_{i n}^{\prime} \theta_{n}=Y_{i}-\tilde{X}_{i}^{\prime} \theta$.
We show in Lemma B. 11 that

$$
\begin{equation*}
\sqrt{n h_{n}}\left(\hat{\theta}_{n}-\theta_{n}\right) \rightarrow_{d} N(0, \Omega), \tag{18}
\end{equation*}
$$

and provide an expression for $\Omega$. The asymptotic normality for $\sqrt{n h_{n}}\left(\hat{\beta}_{n}-\beta_{0}\right)$ then follows as

$$
\sqrt{n h_{n}}\left(\hat{\beta}_{n}-\beta_{0}\right) \rightarrow_{d} N(0, \Sigma),
$$

where $\Sigma=e_{0}^{\prime} \Omega e_{0}$, and $e_{0}$ has a one in the first entry, corresponding to $X$, and zero everywhere else.
We introduce some notation that will be used throughout,

$$
\gamma_{l}=\int_{0}^{\infty} u^{l} k(u) d u
$$

$$
\begin{array}{cc}
\mu_{j}^{+}=\lim _{w \downarrow 0} E\left[Z^{j} \mid W=w\right] & \mu_{j}^{-}=\lim _{w \uparrow 0} E\left[Z^{j} \mid W=w\right], \\
k_{i h_{n}}^{+}=k\left(W / h_{n}\right) 1(W \geq 0) & k_{i h_{n}}^{-}=k\left(W / h_{n}\right) 1(W<0), \\
b_{l j}^{+}=\gamma_{l} \mu_{j}^{+}, b_{l j}^{-}=\gamma_{l} \mu_{j}^{-}, b_{x l j}^{+}=\gamma_{l} \mu_{X j}^{+}, b_{x l j}^{-}=\gamma_{l} \mu_{X j}^{-} .
\end{array}
$$

Lemma B. 1 Under Assumption 4 1-5,

$$
\hat{E}\left[\tilde{X}_{i n} S_{i n}^{\prime}\right] \rightarrow_{p} \Delta_{X}
$$

where

$$
\Delta_{X}=f(0)\left[\begin{array}{cccccccc}
b_{x 00}^{+} & b_{x 01}^{+} & b_{x 10}^{+} & b_{x 11}^{+} & b_{x 00}^{-} & b_{x 01}^{-} & b_{x 10}^{-} & b_{x 11}^{-} \\
b_{00}^{+} & b_{01}^{+} & b_{10}^{+} & b_{11}^{+} & b_{00}^{-} & b_{01}^{-} & b_{10}^{-} & b_{11}^{-} \\
b_{01}^{+} & b_{02}^{+} & b_{11}^{+} & b_{12}^{+} & b_{01}^{-} & b_{02}^{-} & b_{11}^{-} & b_{12}^{-} \\
b_{10}^{+} & b_{11}^{+} & b_{20}^{+} & b_{21}^{+} & 0 & 0 & 0 & 0 \\
b_{11}^{+} & b_{12}^{+} & b_{21}^{+} & b_{22}^{+} & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & b_{10}^{-} & b_{11}^{-} & b_{20}^{-} & b_{21}^{-} \\
0 & 0 & 0 & 0 & b_{11}^{-} & b_{12}^{-} & b_{21}^{-} & b_{22}^{-}
\end{array}\right] .
$$

Proof. Let

$$
\theta_{l j}^{+}=\frac{1}{n h_{n}} \sum_{i=1}^{n}\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} k_{i h_{n}}^{+}, \quad l, j=0,1,2 .
$$

Then, by the change of variables $u=w / h_{n}$,

$$
\begin{aligned}
E\left[\theta_{l j}^{+}\right] & =h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} k_{i h_{n}}^{+}\right] \\
& =\int_{0}^{\infty} u^{l} k(u) \mu_{j}\left(u h_{n}\right) f\left(u h_{n}\right) d u \\
& =f(0) \gamma_{l} \mu_{j}^{+}+o(1)
\end{aligned}
$$

where $\mu_{j}(w)=E\left[Z^{j} \mid W=w\right]$ and the convergence follows by the Dominated Convergence theorem. As for the variance

$$
\begin{aligned}
\operatorname{Var}\left(\theta_{l j}^{+}\right) & \leq\left(n h_{n}^{2}\right)^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{2 l} Z_{i}^{2 j} k_{i h_{n}}^{+2}\right] \\
& =\left(n h_{n}\right)^{-1} \int_{0}^{\infty} u^{2 l} k^{2}(u) \sigma_{j}^{2}\left(u h_{n}\right) f\left(u h_{n}\right) d u \\
& =o(1),
\end{aligned}
$$

again by the Dominated Convergence theorem.
Similarly, define

$$
\theta_{x l j}^{+}=\frac{1}{n h_{n}} \sum_{i=1}^{n}\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} X_{i} k_{i h_{n}}^{+}, \quad l, j=0,1,2 .
$$

Then, by the change of variables $u=w / h_{n}$,

$$
\begin{aligned}
E\left[\theta_{x l j}^{+}\right] & =h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} X_{i} k_{i h_{n}}^{+}\right] \\
& =\int_{0}^{\infty} u^{l} k(u) \mu_{X j}\left(u h_{n}\right) f\left(u h_{n}\right) d u \\
& =f(0) \gamma_{l} \mu_{X j}^{+}+o(1),
\end{aligned}
$$

by the Dominated Convergence theorem. As for the variance

$$
\begin{aligned}
\operatorname{Var}\left(\theta_{x l j}^{+}\right) & \leq\left(n h_{n}^{2}\right)^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{2 l} Z_{i}^{2 j} X_{i}^{2} k_{i h_{n}}^{+2}\right] \\
& =\left(n h_{n}\right)^{-1} \int_{0}^{\infty} u^{2 l} k^{2}(u) \sigma_{X j}^{2}\left(u h_{n}\right) f\left(u h_{n}\right) d u \\
& =o(1)
\end{aligned}
$$

again by the Dominated Convergence theorem. The proof for $\theta_{l j}^{-}$and $\theta_{x l j}^{-}$, which replace $k_{i h_{n}}^{+}$by $k_{i h_{n}}^{-}$, is analogous, and hence omitted.

Lemma B. 2 Under Assumption 4 1-5,

$$
\hat{E}\left[S_{i n} S_{i n}^{\prime}\right] \rightarrow_{p} \Gamma
$$

where

$$
\Gamma=f(0)\left[\begin{array}{cccccccc}
b_{00}^{+} & b_{01}^{+} & b_{10}^{+} & b_{11}^{+} & 0 & 0 & 0 & 0 \\
b_{01}^{+} & b_{02}^{+} & b_{11}^{+} & b_{12}^{+} & 0 & 0 & 0 & 0 \\
b_{10}^{+} & b_{11}^{+} & b_{20}^{+} & b_{21}^{+} & 0 & 0 & 0 & 0 \\
b_{11}^{+} & b_{12}^{+} & b_{21}^{+} & b_{22}^{+} & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & b_{00}^{-} & b_{01}^{-} & b_{10}^{-} & b_{11}^{-} \\
0 & 0 & 0 & 0 & b_{01}^{-} & b_{02}^{-} & b_{11}^{-} & b_{12}^{-} \\
0 & 0 & 0 & 0 & b_{10}^{-} & b_{11}^{-} & b_{20}^{-} & b_{21}^{-} \\
0 & 0 & 0 & 0 & b_{11}^{-} & b_{12}^{-} & b_{21}^{-} & b_{22}^{-}
\end{array}\right] .
$$

Proof. The proof is analogous to that of Lemma B. 1 and hence is omitted.

Lemma B. 3 Under Assumption 4 1-5,

$$
\hat{E}\left[S_{i n} Y_{i}\right] \rightarrow_{p} \Delta_{Y},
$$

where $\Delta_{Y}=f(0)\left(b_{y 00}^{+}, b_{y 10}^{+}, b_{y 01}^{+}, b_{y 11}^{+}, b_{y 00}^{-}, b_{y 10}^{-}, b_{y 01}^{-}, b_{y 11}^{-}\right)^{\prime}, b_{y l j}^{+}=\gamma_{l} \mu_{Y j}^{+}, b_{y l j}^{-}=\gamma_{l} \mu_{Y j}^{-}$.
Proof. The proof is analogous to that of Lemma B. 1 and hence is omitted.
Lemma B. 4 Assume 1, 2 and 4. Then,

$$
\Delta_{Y}=\Delta_{X}^{\prime} \theta_{0}
$$

where $\theta_{0}=\left(\beta_{0}, \eta_{1}, \eta_{2}, 0,0,0,0\right)^{\prime}$.
Proof. By Assumption 4 6, we can write

$$
E\left[H_{i} \mid Z_{i}, W=w\right]:=\alpha_{0 H}(w)+\alpha_{1 H}(w) Z_{i} .
$$

Hence, this last display and Assumption 1 yield

$$
\mu_{Y j}(w)=\beta(w) \mu_{X j}(w)+\alpha_{0 H}(w) \mu_{j}(w)+\alpha_{1 H}(w) \mu_{j+1}(w) .
$$

Taking right and left limits at $w=0$ imples the desired equality $\Delta_{Y}=\Delta_{X}^{\prime} \theta_{0}$, where $\eta_{1}=\alpha_{0 H}(0)$ and $\eta_{2}=\alpha_{1 H}(0)$.

The previous Lemmas show the consistency of $\hat{\beta}$, since

$$
\hat{\theta}_{n} \rightarrow_{p}\left(\Delta_{X} \Gamma^{-1} \Delta_{X}^{\prime}\right)^{-1} \Delta_{X} \Gamma^{-1} \Delta_{Y}=\theta_{0}
$$

We prove several Lemmas that will yield the asymptotic normality of $\sqrt{n h_{n}}\left(\hat{\theta}_{n}-\theta_{n}\right)$, and hence of $\sqrt{n h_{n}}\left(\hat{\beta}_{n}-\beta_{0}\right)$.

Define the function

$$
\begin{aligned}
\zeta_{H}(w, z) & =\alpha_{0 H}(w)+\alpha_{1 H}(w) z-\alpha_{0 H}^{+}+\alpha_{1 H}^{+} z \\
& -\left(\dot{\alpha}_{0 H}^{+}+\dot{\alpha}_{1 H}^{+} z\right) w-\frac{1}{2}\left(\ddot{\alpha}_{0 H}^{+}+\ddot{\alpha}_{1 H}^{+} z\right) w^{2},
\end{aligned}
$$

where $\dot{\alpha}_{0 H}^{+}=\lim _{w \downarrow 0} \partial \alpha_{0 H}(w) / \partial w$ and $\ddot{\alpha}_{0 H}^{+}=\lim _{w \downarrow 0} \partial^{2} \alpha_{0 H}(w) / \partial w^{2}$, and similarly for $\alpha_{1 H}$. We use later that

$$
\sup _{0<w<M h_{n}}\left|\zeta_{H}(w, z)\right|=o\left(h_{n}^{2}\right)(1+|Z|) .
$$

The function $\zeta_{H}(w, z)$ is the Taylor's remainder of order two of $E\left[H_{i} \mid Z_{i}, W=w\right]:=\alpha_{0 H}(w)+$ $\alpha_{1 H}(w) Z_{i}$ around $w=0$. We can also relate the coefficients in this expansion with the coefficients in $\eta$. Following the arguments above, it can be shown that

$$
\tilde{\eta}=\arg \min _{\beta, \eta} \sum_{i=1}^{n}\left(H_{i}-\eta^{\prime} C_{i}\right)^{2} k_{h_{n}}\left(W_{i}\right) .
$$

estimates consistently $\eta$. Thus,

$$
\begin{aligned}
& \eta_{1}=\alpha_{0 H}(0), \eta_{2}=\alpha_{1 H}(0), \eta_{3}=\dot{\alpha}_{0 H}(0), \\
& \eta_{4}=0, \eta_{5}=\dot{\alpha}_{1 H}(0), \eta_{6}=0 .
\end{aligned}
$$

Recall $U_{i}=Y_{i}-\tilde{X}_{i}^{\prime} \theta$. Then, from the definitions above

$$
\begin{aligned}
E\left[U_{i} \mid Z_{i}, W\right] & =E\left[H_{i} \mid Z_{i}, W\right]-\alpha_{0 H}^{+}+\alpha_{1 H}^{+} Z-\dot{\alpha}_{0 H}^{+} W+\dot{\alpha}_{1 H}^{+} Z W \\
& =\frac{1}{2}\left(\ddot{\alpha}_{0 H}^{+}+\ddot{\alpha}_{1 H}^{+} Z_{i}\right) W_{i}^{2}+\zeta_{H}\left(W_{i}, Z_{i}\right) .
\end{aligned}
$$

The following Lemmas make use of Assumptions 1, 2 and 4.

## Lemma B. 5 (Numerator: Expectation)

$$
E\left[\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} U_{i} k_{i h_{n}}\right] \rightarrow_{p} \frac{1}{2} f(0) h_{n}^{2}\left(b_{U}+o(1)\right),
$$

where

$$
b_{U}=\left[\begin{array}{c}
\gamma_{2}\left(\ddot{\alpha}_{0 H}^{+}+\ddot{\alpha}_{0 H}^{+} \mu_{1}^{+}\right) \\
\gamma_{2}\left(\ddot{\alpha}_{0 H}^{+} \mu_{1}^{+}+\ddot{\alpha}_{0 H}^{+} \mu_{2}^{+}\right) \\
\gamma_{3}\left(\ddot{\alpha}_{0 H}^{+}+\ddot{\alpha}_{0 H}^{+} \mu_{1}^{+}\right) \\
\left.\gamma_{3} \ddot{\alpha}_{0 H}^{+} \mu_{1}^{+}+\ddot{\alpha}_{0 H}^{+} \mu_{2}^{+}\right) \\
\gamma_{2}\left(\ddot{\alpha}_{0 H}^{-}+\ddot{\alpha}_{0 H}^{+} \mu_{1}^{-}\right) \\
\gamma_{2}\left(\ddot{\alpha}_{0 H}^{-} \mu_{1}^{-}+\ddot{\alpha}_{0 H}^{-} \mu_{2}^{+}\right) \\
\gamma_{3}\left(\ddot{\alpha}_{0 H}^{-}+\ddot{\alpha}_{0 H}^{-} \mu_{1}^{+}\right) \\
\gamma_{3}\left(\ddot{\alpha}_{0 H}^{-} \mu_{1}^{+}+\ddot{\alpha}_{0 H}^{-} \mu_{2}^{+}\right)
\end{array}\right] .
$$

Proof. Let

$$
u_{l j}^{+}=\frac{1}{n h_{n}} \sum_{i=1}^{n}\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} U_{i} k_{i h_{n}}^{+}, \quad l, j=0,1 .
$$

Then, write

$$
\begin{aligned}
E\left[u_{l j}^{+}\right] & =h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} U_{i} k_{i h_{n}}^{+}\right] \\
& =h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j}\left(\frac{1}{2}\left(\ddot{\alpha}_{0 H}^{+}+\ddot{\alpha}_{1 H}^{+} Z_{i}\right) W_{i}^{2}+\zeta_{H}\left(W_{i}, Z_{i}\right)\right) k_{i h_{n}}^{+}\right] \\
& =h_{n}^{-1} \frac{1}{2} \ddot{\alpha}_{0 H}^{+} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} W_{i}^{2} k_{i h_{n}}^{+}\right]+h_{n}^{-1} \frac{1}{2} \ddot{\alpha}_{1 H}^{+} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j+1} W_{i}^{2} k_{i h_{n}}^{+}\right] \\
& +h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} \zeta_{H}\left(W_{i}, Z_{i}\right) k_{i h_{n}}^{+}\right] .
\end{aligned}
$$

By the change of variables $u=w / h_{n}$,

$$
\begin{aligned}
h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} W_{i}^{2} k_{i h_{n}}^{+}\right] & =h_{n}^{2} \int_{0}^{\infty} u^{l+2} k(u) \mu_{j}\left(u h_{n}\right) f\left(u h_{n}\right) d u \\
& =h_{n}^{2} \mu_{j}^{+} f\left(0^{+}\right) \gamma_{l+2}+o(1),
\end{aligned}
$$

and similarly

$$
h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j+1} W_{i}^{2} k_{i h_{n}}^{+}\right]=h_{n}^{2} \mu_{j+1}^{+} f\left(0^{+}\right) \gamma_{l+2}+o(1) .
$$

On the other hand, assume without loss of generality that $[-M, M]$ contains the support of $k$, so that

$$
h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} \zeta_{H}\left(W_{i}, Z_{i}\right) k_{i h_{n}}^{+}\right]=o\left(h_{n}^{2}\right) .
$$

The proof for the left limit version is analogous, and hence omitted.

## Lemma B. 6 (Numerator: Conditional Expectation)

$$
\frac{1}{n h_{n}} \sum_{i=1}^{n} E\left[S_{i n} U_{i} k_{i h_{n}} \mid W_{i}, Z_{i}\right]=\frac{1}{n h_{n}} \sum_{i=1}^{n} E\left[S_{i n} U_{i} k_{i h_{n}}\right]+o_{p}\left(h_{n}^{2}\right) .
$$

Proof. We have

$$
\begin{aligned}
\frac{1}{n h_{n}} \sum_{i=1}^{n} E\left[S_{i n} U_{i} k_{i h_{n}} \mid W_{i}, Z_{i}\right] & =\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}}\left(\frac{1}{2}\left(\ddot{\alpha}_{0 H}^{+}+\ddot{\alpha}_{1 H}^{+} Z_{i}\right) W_{i}^{2}+\zeta_{H}\left(W_{i}, Z_{i}\right)\right) \\
& =\frac{1}{2} \ddot{\alpha}_{0 H}^{+} \frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}} W_{i}^{2}+\frac{1}{2} \ddot{\alpha}_{1 H}^{+} \frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}} Z_{i} W_{i}^{2} \\
& +\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}} \zeta_{H}\left(W_{i}, Z_{i}\right) .
\end{aligned}
$$

Observe that

$$
\begin{aligned}
\operatorname{Var}\left(\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}} W_{i}^{2}\right) & =\left(n h_{n}^{2}\right)^{-1} \operatorname{Var}\left(S_{i n} k_{i h_{n}} W_{i}^{2}\right) \\
& \leq C\left(n h_{n}\right)^{-1} h_{n}^{-1} E\left[S_{i n} S_{i n}^{\prime} k_{i h_{n}}^{2} W_{i}^{4}\right] \\
& =O\left(\left(n h_{n}\right)^{-1} h_{n}^{4}\right) \\
& =o(1),
\end{aligned}
$$

since for $l, j=0,1,2$

$$
\begin{aligned}
h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} k_{i h_{n}}^{+2} W_{i}^{4}\right] & =h_{n}^{4} \int_{0}^{\infty} u^{l} k^{2}(u) \mu_{j}\left(u h_{n}\right) f\left(u h_{n}\right) d u \\
& =h_{n}^{4} \mu_{j}^{+} f\left(0^{+}\right) v_{l}+o(1),
\end{aligned}
$$

where

$$
v_{l}=\int_{0}^{\infty} u^{l} k^{2}(u) d u,
$$

and similarly

$$
h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} k_{i h_{n}}^{-2} W_{i}^{4}\right]=h_{n}^{4} \mu_{j}^{-} f\left(0^{-}\right) v_{l}+o(1)
$$

Likewise,

$$
\operatorname{Var}\left(\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}} Z_{i} W_{i}^{2}\right)=o(1) .
$$

and

$$
\operatorname{Var}\left(\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}} \zeta_{H}\left(W_{i}, Z_{i}\right)\right)=o(1) .
$$

Note that

$$
\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}}^{+}\left(U_{i}-E\left[U_{i} \mid W_{i}, Z_{i}\right]\right)=\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{i n} k_{i h_{n}}^{+} \varepsilon_{U_{i}},
$$

where $\varepsilon_{U_{i}}=U_{i}-E\left[U_{i} \mid W_{i}, Z_{i}\right]$ denotes the regression error. Then, we have the following result.

## Lemma B. 7 (Numerator: Conditional Variance)

$$
\operatorname{Var}\left(\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{+i n} k_{i h_{n}} \varepsilon_{U_{i}}\right)=\frac{1}{n h_{n}} \Sigma_{U^{+}}+o(1),
$$

where

$$
\begin{gathered}
\Sigma_{U^{+}}=f\left(0^{+}\right)\left[\begin{array}{cccc}
v_{0} & v_{0} q_{1}^{+} & v_{2} & v_{2} q_{1}^{+} \\
v_{0} q_{1}^{+} & v_{0} q_{2}^{+} & v_{2} q_{1}^{+} & v_{2} q_{2}^{+} \\
v_{2} & v_{2} q_{1}^{+} & v_{4} & v_{4} q_{1}^{+} \\
v_{2} q_{1}^{+} & v_{2} q_{2}^{+} & v_{4} q_{1}^{+} & v_{4} q_{2}^{+}
\end{array}\right], \\
v_{l}=\int_{0}^{\infty} u u^{l} k^{2}(u) d u \text { and } q_{j}^{+}=\lim _{w \downarrow 0} E\left[Z^{2 j} \varepsilon_{U_{i}}^{2} \mid W=w\right] .
\end{gathered}
$$

Proof. Consider the generic term, for $l, j=0,1$

$$
\frac{1}{n h_{n}} \sum_{i=1}^{n}\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} k_{i h_{n}}^{+} \varepsilon_{U_{i}},
$$

and its variance, which equals

$$
\begin{aligned}
\left(n h_{n}\right)^{-1} h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{2 l} Z_{i}^{2 j} k_{i h_{n}}^{+2} \varepsilon_{U_{i}}^{2}\right] & =\left(n h_{n}\right)^{-1} \int_{0}^{\infty} u^{2 l} k^{2}(u) q_{j}\left(u h_{n}\right) f\left(u h_{n}\right) d u \\
& =\left(n h_{n}\right)^{-1} f\left(0^{+}\right) q_{j}^{+} v_{2 l}+o(1)
\end{aligned}
$$

where $q_{j}(w)=E\left[Z^{2 j} \varepsilon_{U_{i}}^{2} \mid W=w\right]$.
Similarly, we have the following result, which proof is the same as in the previous lemma.

## Lemma B. 8

$$
\operatorname{Var}\left(\frac{1}{n h_{n}} \sum_{i=1}^{n} S_{-i n} k_{i h_{n}} \varepsilon_{U_{i}}\right)=\frac{1}{n h_{n}} \Sigma_{U^{-}}+o(1),
$$

where

$$
\begin{aligned}
\Sigma_{U^{-}}=f\left(0^{-}\right) & {\left[\begin{array}{cccc}
v_{0} & v_{0} q_{1}^{-} & v_{2} & v_{2} q_{1}^{-} \\
v_{0} q_{1}^{-} & v_{0} q_{2}^{-} & v_{2} q_{1}^{-} & v_{2} q_{2}^{-} \\
v_{2} & v_{2} q_{1}^{-} & v_{4} & v_{4} q_{1}^{-} \\
v_{2} q_{1}^{-} & v_{2} q_{2}^{-} & v_{4} q_{1}^{-} & v_{4} q_{2}^{-}
\end{array}\right], } \\
q_{j}^{-} & =\lim _{w \uparrow 0} E\left[Z^{2 j} \varepsilon_{U_{i}}^{2} \mid W=w\right] .
\end{aligned}
$$

Define

$$
\Sigma_{U}=\left[\begin{array}{cc}
\Sigma_{U^{+}} & 0 \\
0 & \Sigma_{U^{-}}
\end{array}\right]
$$

## Lemma B. 9 (Numerator: Conditional CLT)

$$
\left(n h_{n}\right)^{-1 / 2} \sum_{i=1}^{n} S_{i n} k_{i h_{n}} \varepsilon_{U_{i}} \rightarrow_{d} N\left(0, \Sigma_{U}\right) .
$$

Proof. Consider a generic term for $l, j=0,1$

$$
\frac{1}{\sqrt{n h_{n}}} \sum_{i=1}^{n}\left(\frac{W_{i}}{h_{n}}\right)^{l} Z_{i}^{j} k_{i h_{n}}^{+} \varepsilon_{U_{i}} .
$$

We apply Lyapounov with third absolute moment. By the lemma on the asymptotic variance, we need to establish

$$
\left(n h_{n}\right)^{-1 / 2} h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{3 l} Z_{i}^{3 j} k_{i h_{n}}^{+3} \varepsilon_{U_{i}}^{3}\right]=o(1) .
$$

But note that, defining $s_{j}(w)=E\left[Z^{3 j} \varepsilon_{U_{i}}^{3} \mid W=w\right]$,

$$
\begin{aligned}
h_{n}^{-1} E\left[\left(\frac{W_{i}}{h_{n}}\right)^{3 l} Z_{i}^{3 j} k_{i h_{n}}^{+3} \varepsilon_{U_{i}}^{3}\right] & =\int_{0}^{\infty} u^{3 l} k^{3}(u) s_{j}\left(u h_{n}\right) f\left(u h_{n}\right) d u \\
& =O(1)
\end{aligned}
$$

The same holds for the left limit part.

## Lemma B. 10 (Numerator: Unconditional CLT)

$$
\left(n h_{n}\right)^{-1 / 2} \sum_{i=1}^{n} S_{i n} U_{i} k_{i h_{n}}-\frac{\left(n h_{n}\right)^{1 / 2} h_{n}^{2}}{2} f(0) b_{U} \rightarrow_{d} N\left(0, \Sigma_{U}\right) .
$$

Proof. It follows from previous Lemmas.
Lemma B. 11 (Main CLT)

$$
\sqrt{n h_{n}}\left(\hat{\theta}_{n}-\theta_{n}\right) \rightarrow_{d} N(0, \Omega),
$$

where

$$
\Omega=\left(\Delta \Gamma^{-1} \Delta^{\prime}\right)^{-1} \Delta \Gamma^{-1} \Sigma_{U} \Gamma^{-1} \Delta^{\prime}\left(\Delta \Gamma^{-1} \Delta^{\prime}\right)^{-1}
$$

Proof. It follows from previous Lemmas.
